

# Sequencing and Analyses of All Known Human Rhinovirus Genomes Reveal Structure and Evolution 

\author{

#### Abstract

Infection by human rhinovirus (HRV) is a major cause of upper and lower respiratory tract disease worldwide and displays considerable phenotypic variation. We examined diversity by completing the genome sequences for all known serotypes ( $n=99$ ). Superimposition of capsid crystal structure and optimal-energy RNA configurations established alignments and phylogeny. These revealed conserved motifs; clade-specific diversity, including a potential newly identified species (HRV-D); mutations in field isolates; and recombination. In analogy with poliovirus, a hypervariable $5^{\prime}$ untranslated region tract may affect virulence. A configuration consistent with nonscanning internal ribosome entry was found in all HRVs and may account for rapid translation. The data density from complete sequences of the reference HRVs provided high resolution for this degree of modeling and serves as a platform for full genome-based epidemiologic studies and antiviral or vaccine development.

}

Human rhinovirus (HRV), the disease agent for the common cold, is responsible for $\sim 50 \%$ of asthma exacerbations and is one of the factors that can direct the infant immune system toward an asthmatic phenotype (1-4). Direct and indirect costs from the common cold and related complications in asthmatics amount to an estimated $\sim \$ 60$ billion per year in the United States (5, Ø). HRVs are single-stranded, positive-sense RNA enteroviruses in the Picornaviridae family and have been cataloged primarily by capsid serotyping relative to a historical repository of 99 strains, obtained from clinical specimens. HRVs are classified by their use of either intercellular adhesion molecule-1 (ICAM-1) ( 88 major viruses) or low-density lipoprotein receptor (LDLR) (11 minor viruses) as their receptor for cell entry (7). They have also been characterized by composite sensitivities across a panel of potential therapeutics (8) that have been used to parse the strains into two related drug-reactivity groups. The partial sequences of viral capsid-coding regions, noncoding regions, and a limited number of complete genomes have resulted in a division of the original 99 strains into two species: HRV-A (containing 74 serotypes) and HRV-B (containing 25 serotypes).

Recently, a number of previously unknown HRV-like sequences were detected in patients with influenza-like illnesses associated with severe respiratory compromise (9-11). The newly identified

[^0]viruses have not been cultured, but their sequences indicate that they likely represent a third (HRV-C) species. The lack of whole-genome sequence data for the full cohort of HRVs has made it difficult to understand basic molecular and evolutionary characteristics of the viruses and has hampered investigations of the epidemiology of upper respiratory tract infections and asthma epidemics. To define the extent and nature of HRV diversity and their evolution, we sequenced the genomes for every previously undetermined HRV in the reference repository, completing the full set of 99 serotypes, as well as 10 additional field samples.

Genome sequences and alignments. Modifications (12) were made to the sequence-independent, single-primer amplification (SISPA) method (13) to determine the complete genomes of 70 HRVs from the reference repository, as well as 10 nasal-wash samples from patients with HRV upper respiratory tract infections. We sequenced these viruses to an average of sixfold coverage for each of the $\sim 7-\mathrm{kb}$ genomes. To provide phylogenetic accuracy for these organisms with relatively small genomes and (often) high degrees of sequence similarity, a stringent approach was taken for aligning the sequences. The initial sequence fits for the polyproteins were performed on the basis of superimposition of the amino acid sequences within virion crystal structure maps (14) and supplemented with additional structure data from other viral proteins. In a stepwise manner, profile hidden Markov models (HMM) augmented the founder set with the remaining sequences (13). The published sequences (including redundant determinations) for the remaining serotypes were added so that the final collection consisted of 138 full-length HRV genomes, including at least one representative for each of the 99 original strains, 10 field samples, and 7 HRV-C strains (table S1). The genome-length RNA and polyprotein alignments for all considered sequences
are provided in tables S2 and S3. Regardless of species, all HRVs were found to have similar average base compositions. They are rich in A ( 31 to $34 \%$ ) and $\mathrm{U}(25$ to $30 \%$ ) but low in G (19 to 22\%) and C (18 to $22 \%$ ). The third codon positions have the highest composition skew. An identity matrix for the polyproteins (fig. S 1 ) shows that the average amino acid identity between pairs of HRV-C strains is slightly more diverse ( $78 \%$ identity, range $68 \%$ to $95 \%$ ) than among the HRV-A ( $80 \%$, range $64 \%$ to $99 \%$ ) or HRV-B ( $83 \%$, range $75 \%$ to $97 \%$ ). The lack of broader diversity suggests that all HRVs are in a stable status for maintaining selection for certain traits, yet still have mutational flexibility for escape from immune responses.

Picornaviruses encode a single open reading frame (ORF) representing about $90 \%$ of the RNA length. Translation produces a polyprotein ( $\sim 215$ kD for HRV), subsequently cleaved in a viral protease-dependent cascade to form the 11 to 12 mature viral proteins required to initiate and sustain an infection (fig. S2A). Local and global RNA structures play established roles in HRV biology; however, the extent, character, and relatedness of serotype-specific $5^{\prime}$ - and $3^{\prime}$ UTR (untranslated region) variation are unknown. The role of this variability has thus not been related to function by modeling techniques or in vivo approaches. Our alignment methods included optimal energy RNA structure considerations (15) and were therefore sensitive to potential differences among the HRVs in the $5^{\prime}$ - and $3^{\prime}$ UTRs.

HRV RNA structures. All enteroviruses encode 5'-terminal cloverleaf-like motifs (CLs) that bind viral and cellular proteins for the initiation of RNA synthesis and also help convert infecting genomes from translation to replication templates. The HRV CLs [80 to 84 bases (b)] were predicted in every sequence with minimal structural variation among the species (representative structures are shown in Fig. 1A and additional structures in fig. S3). Immediately $3^{\prime}$ to the CL, all HRVs were found to share an unusual pyrimidine-rich spacer segment with short oligo(C) and oligo(U) units interspersed with As (blue boxes, Fig. 1A and fig. S3A). The HRV-A have the shortest tracts ( 11 to 22 b ) and HRV-B the longest ( 22 to 50 b). Nearly every HRV displayed a unique sequence in this region, and we identified unexpected variation even among isolates of the same serotype (Fig. 1A and fig. S3A). The equivalent genome location in poliovirus ( 10 b ) interacts with poly(C)-binding protein 2 and is involved in the determination of the polio neurovirulent potential. The analogous regions in aphthoviruses or cardioviruses have homopolymeric poly(C) or poly(UC) tracts, the deletion of which markedly attenuates the virus through an RNA-activated protein kinase activation-dependent mechanism (10). If the HRV $5^{\prime}$ spacer tracts are functional analogs to those of these other picornaviruses, then it is possible that the pathogenic potential of an individual HRV may also be encoded, in part, by this region.

Picornaviruses use internal ribosome entry sites (IRESs) to mediate translation initiation of their
polyprotein ORFs. The IRESs of all enteroviruses (termed type 1 IRESs) are thought to bind $40 S$ ribosomal subunits internally within their 5'UTR and to then scan additional nucleotides to find the proper initiator AUG (17). Our modeling of the known serotypes confirms that all HRV IRESs start just $3^{\prime}$ to the pyrimidine-rich spacer tract. We found that the internal IRES sequences are highly conserved, with an average nucleotide identity of $82 \%$. Indeed, this region of the genome has the greatest degree of identity among all HRV (fig. S2B), exceeding $95 \%$ for regional motifs within the IRES. However, we also observed that the dominant IRES sequence conservation did not extend completely to the initiator AUG and that for the 18 to 40 bases $5^{\prime}$ - to this codon, the region scanned by ribosomes, there was little species-specific conservation ( $<60 \%$ nucleotide identity). Despite this, our folding predictions configured every one of these regions into virtually the same RNA motif, which suggests that this structure is conserved even when the underlying nucleotides are not (Fig. 1B and fig. S3B).

Near the bottom of a long [ 15 to 20 base pair (bp)] minimum energy unbranched stem, the ORF AUG was invariably paired with a conserved upstream noncoding AUG (green boxes, Fig. 1B), marking the $3^{\prime}$ boundary of the IRES, and the normal launch point for $40 S$ scanning. Every HRV genome fold maintains this pairing. We predict that HRVs use the proximity of these AUGs to orient the $40 S$ for direct transfer to the proper codon, without the need for scanning through the intervening nucleotides. The sequence and length variation between the AUGs was consistent with the idea that ribosomes would bypass this region entirely if they jump from one AUG to the other. This IRES folding is essentially a bait-and-switch mechanism, which we predict may enhance HRV translation competitiveness. This paired AUG motif is unique to HRV and is not found in other enteroviruses (e.g., poliovirus).

The HRV 3'UTRs ( 40 to 60 b) begin with the ORF termination codon and extend to the genetically encoded poly(A) tail. The ORF terminators themselves (solid red boxes in Fig. 1C and fig. S3D) included UAG, UAA, and UGA codons. The codon selection often differed among isolates from the same serotype. Multiple additional terminators ( $\tan$ boxes), in and out of the ORF, were identified that punctuated each segment (3 to 9 per UTR). Despite large differences ( $>40 \%$ ) in nucleotide identity (Fig. 1C), it was noted that all HRVs maintain a 13 - to 16 -bp unbranched stem, covering 67 to $88 \%$ of the $3^{\prime}$ UTR, immediately abutting the poly(A) tail (see also fig. S3D). Some 3' stems have small interior loops, but nearly all, except for the unusual sequences of clade-D, present 5 -base terminal loops, anchored with apical U-G or U-A pairs. Inevitably, the 3 ' sides of these terminal loops display UAG or UGA terminator codons, which may or may not synchronize with the local ORF. The function of these $3^{\prime}$ stems is unknown, but such conservation is usually indicative of a putative protein recognition motif (such as translation termina-
tion factors) or, alternatively, an RNA:RNA tertiary interaction between the terminal-loop segment and a different (unknown) region of the genome.

Phylogenetic relationships of the HRV. Multiple methods were used to compute and compare phylogenetic trees for the aligned RNA and protein data. Figure 2 is a neighbor-joining consensus tree (18), which considered the $5^{\prime}$ - and $3^{\prime}$ UTRs and the first and second codon positions for the RNA genomes. All major nodes of the tree topology were stable over a range of calculation parameters, regardless of whether they invoked minimum evolution, parsimony, unweighted pair group method with arithmetic mean, or maximum likelihood (ML) methods. (See fig. S6A for ML tree with bootstrap, likelihood ratio tests, and comparison to the neighbor-joining tree.) Statistical comparisons were performed between the ML tree generated from the full genomes and the ML constrainedtopology trees generated from capsid sequences that have been used as a surrogate for serotypes (fig. S6, A to C) (13), with the null hypothesis that topologies of these limited-sequence trees were the same as that of the full genome-based tree. The approximately unbiased (AU) test calculated from
the multiscale bootstrap $P$ values for the capsid VP1 and VP0 trees were $<10^{-69}$, strongly rejecting the null hypothesis. In a similar manner, ML constrained-topology trees generated from IRES and 3D-polymerase sequences were not consistent with the full genome tree (fig. S6, A and B). Additional statistical tests also confirmed these results from the AU (fig. S6, B and C) for all four of the constrained-topology trees. Taken together, these results suggest that trees based on sequences from small, albeit biologically important, regions of the HRV genome have a limited capacity to reflect the evolutionary relationships and underlying diversity of HRVs. The tree shown in Fig. 2 also accurately represents parallel calculations on the aligned polyprotein dataset (p-distances differed by $<2 \%$ ). All aligned full-length sequences contributed to the tree calculations, but published sequences (noted with asterisks on Fig. 2) are shown only as needed, to complete the cohort of reference serotypes. (Were the redundant published sequences illustrated, without exception they would lie on the same-serotype branches, with p-distances $<0.5 \%$.) The outer rings of this figure designate major (M: ICAM-1) or minor (m: LDLR) receptor preferences, and also each

Fig. 1. Genome-wide optimal energy RNA configurations for select motifs representative of each HRV species. (A) All HRVs display characteristic 5'UTR CL elements with minimal predicted structural variation (blue boxes). (B) The alignments and predicted structures of the IRES of HRVs reveal a bait-and-switch arrangement for initiation of translation. A stem-pairing AUG (light green box) is found for each species, but a highly variable region of intervening sequence near the initiator AUG (dark green box) was noted. (C) HRV 3'UTRs have a unique unbranched stem motif before the poly-A tail. The left-most codon (red box, white text) is the ORF terminator. Other boxes highlight additional terminators (tan boxes), including a characteristic codon (tan box, red text) found in the apical loop.
strain's small-molecule drug reactivity group (" 1 " or " 2 ") (8). The tree is shown rooted with three outgroup sequences from the Human Enterovirus $C$ species (poliovirus 1 m , coxsackieviruses al3 and a21), but the use of five additional outgroups had no effect on overall tree topology or HRV p-distances (fig. S6). The field samples (i.e., f01 to f10) were assigned tentative serotype names on the basis of capsid similarity relative to the known reference strains. Although some of the full genomes from these samples proved close to their repository cognates, a divergence in sequence for several strains was noted.

According to our tree(s), HRV-A and HRV-C share a common ancestor, which is a sister group to the HRV-B. Although the HRV-C clade currently has only seven full sequences, its genetic origin is clearly different from the reference set, and our phylogeny indicates that these represent a third HRV species, as has been recommended to the International Committee on Taxonomy of Viruses (19). The HRV-C have yet to be cultured or assessed for immunological cross-reactivity, but the sequence
space occupied by the available samples suggests that there may be many additional HRV-C strains awaiting discovery. Distance extrapolations relative to the new full reference cohort predict that HRV-C may have an even broader range of serotypes than the original 99 , of which each confers only limited immunologic cross-protection to another.

A separate phylogenic finding was the unexpected basal divergence within HRV-A of a small $(n=3)$ group of distinct strains, denoted clade $\mathrm{D}(20)$. Although the major basis for discriminating clade D from other HRV-A lies in their general, genome-length sequence divergence, these particular isolates have RNA elementssuch as the cis-acting replication element, the $3^{\prime}$ UTR terminal loop feature (see above and fig. S3), and local insertions/deletions and sequence motifs - that are somewhat atypical of other HRV-A strains. Some of the distinguishing characteristics are highlighted in fig. S4. Among all other major A clades, and major B clades, none have p-distances ( $>10 \%$ ) that segregate them so distinctly. We are cautious in proposing clade D

Fig. 2. A neighbor-joining ( NJ ) phylogenetic tree showing relationships between all known HRV serotypes created on the basis of full genome sequences. The HEV-C sequences (poliovirus 1M, coxsackievirus a13, and coxsackievirus a21) were used as outgroups. Branch lengths are proportional to similarity (p-distance). Key nodes on this tree are annotated with NJ bootstrap values (percentage of 2000 sampled trees). Asterisks in the strain names identify sequences obtained from published data (table S1). All other taxa are from this study. Letters in the outer rings designate whether that virus uses the major ( $M$ ) ICAM-1 receptor or the minor ( m ) LDLR receptor ( 7 ) and whether its relative reactivity was more like group " 1 " or group " 2 " (if known) toward a panel of small-molecule antiviral compounds (8).
as a fourth species (HRV-D), but the phylogenetic evidence (Fig. 2) and sequence characteristics (figs. S3 and S4) are highly suggestive. Other early topological divisions within HRV-A separate a major clade composed of 10 serotypes (counterclockwise, hrv-20 through hrv-12) from a second grouping composed of $\sim 12$ miniclades representing 61 serotypes (counterclockwise, hrv-$89-\mathrm{f} 09$ through hrv-100). These particular relationships were not readily apparent when only partial genome sequences were examined ( 21,22 ). Fig. S6 shows a comparison of results from trees constructed with whole genomes, VP4/VP2, and VP1 sequence. Neither of the trees derived from these shorter sequences revealed the miniclades, clade D, or multiple other features. We thus contend that comparison of full-genome data, the context wherein evolutionary events occur, most likely provides the defining relationships among the HRVs, allows a more comprehensive assessment of strain diversity, and allows for more accurate historical extrapolations. The phylogenetic diversity we describe at the whole-genome level is consistent with the clinical heterogeneity of HRV infections in humans ( $1,3,4$ ), although mapping specific clinical characteristics (i.e., incubation period, severity, respiratory compromise, and pro-asthmatic phenotypes) to responsible genomic regions will require additional field isolates from a large number of patients with multiple traits. Given the genome-wide diversity we have documented (e.g., $5^{\prime}$ spacer elements, ORF start, protease, $3^{\prime}$ UTRs), clinically relevant relationships may well depend on comparisons from multiple genome regions.

Recombination in HRV. Results from earlier sequencing of a subset of HRV reference genomes concluded that RNA recombination was not a major mechanism for $\operatorname{HRV}$ diversity $(23,24)$ and asserted that known isolates were independently segregating entities. We have reevaluated the potential for recombination by scanning the full reference set and the new field strains with a suite of recombination detection programs (25) relying on phylogenetic distance and sequence similarity. Stringent criteria ( $P<0.00001$ from two or more analyses modes) identified 23 genomes with probable origins resulting from at least 12 independent recombination events. Figure 3A shows representative data indicating that hrv-46 arose by recombination between hrv-53 (major parent) and hrv-80 (minor parent). Within the hrv-46 genome, nucleotides 32 to 3222 are most similar to hrv- 80 , whereas the rest of the genome (nucleotides 3223 to 7200) is common to hrv-53. The result is consistent with this trio's computed phylogenetic relationship (Fig. 2), placing the major parent (hrv-53) and the daughter (hrv-46) in the same clade and the minor parent (hrv-80) in a different, nearby clade. Results for all 23 identified recombination scenarios are summarized in Table 1. [See also (13) and table S4.] Of the recombination locales suggested by these events, the majority ( 10 of 12 ) involve the $5^{\prime}$ UTR or the adjacent capsid genes, which seemingly have been collectively rearranged to produce at least 20 separate progeny strains. Among the

Fig. 3. Recombination of HRVs creates additional serotypes. (A) Representative results showing that hrv-46 arose from a recombination of hrv-53 (major parent) and hrv-80 (minor parent). Shown are normalized pairwise identities between each parent and the daughter hrv (purple and green) and the two parents (yellow). As indicated, hrv-46 nucleotides 32 to 3222 are from hrv-80, and nucleotides 3223 to 7200 are from hrv-53. (B) Recombination with an ancestor of hrv-54-f05 has resulted in seven serotype progeny. Each parental hrv is shown as a solid color. The contribution of each parent is proportional to the area of its color in the offspring. See Table 1 and table S 4 for nucleotide boundaries and results from other recombination events.

Table 1. Recombination events in HRV serotypes. The $P$ value listed is the lowest obtained. See table S4 for full data and $P$ values.

| hrv-84 | hrv-37 | hrv-93 | 5'UTR, VP4 | $1.500 \times 10^{-10}$ |
| hrv-84 | hrv-37 | hrv-97 | 5'UTR, VP4 | $1.500 \times 10^{-10}$ |

138 full-length sequences, hrv-54 (or its ancestor) was apparently the most active in recombination. Field strain hrv-54-f05 links closely to three separate events (see Fig. 3B), contributing to at least seven different serotype progeny. In confirmation studies, we used a progressive alignment method for the HRV genomes (13), then repeated the suite of recombination detection programs. Of the 23 recombination events from the HMM alignment (Table 1), 19 were also found after the progressive alignment, although in some cases different major and/or minor parents were selected from within the same closely related clade (table S4).

Although the sequence fingerprints clearly trace these ancestral patterns, nevertheless all extant progeny also showed evidence of subsequent sequence divergence within the exchanged regions. Recombination was not identified between isolates from different species (i.e., HRV-A and HRV-B), but receptor binding preferences between ICAM and LDLR apparently presented no barriers to exchange. Major group hrv-54 and minor group hrv-29, for example, both contributed to the common ancestor of the minor group viruses, hrv-31 and hrv-47. These results, particularly for HRVs with different receptor preferences and those from distant clades, such as the parents hrv-21 and hrv-65, suggest that coinfection of the host with multiple parental strains is not uncommon and may lead to variant progeny with different biological properties. Our field isolates also deviated from the reference sequences in a manner that was not confined to any specific portion of the genome. In fact, field strain deviation relative to the reference isolates (for example, hrv-52-f01 versus hrv-52 differ by 838 nucleotides) was frequently greater than that observed between pairs of characterized serotypes (hrv-44 and hrv-29 differ by 385 nucleotides). Indeed, field samples of the same serotype collected from the same geographical region within 1 year showed marked variability (tables S2, S3, and S5). The propensity for such variation could underlie the marginal efficacy, or lack of efficacy, of anti-HRV therapeutics in clinical trials $(26,27)$. Given our reference set of full genomes, along with the means to rapidly sequence full genomes from field samples, new strategies may become apparent to engineer cladespecific agents by targeting their commonalities.

Conclusions. Our data complete and define the full set of genome-length sequences in the canonical reference repository of 99 HRV-A and HRV-B serotypes. Alignment and examination of these genomes confirmed species-specific sequence and RNA structural elements that differentiate the HRV-A and HRV-B from newly described HRV-C and further suggest that the HRV-A serotypes harbor a distinct, uncharacteristic clade, which may represent a fourth species (HRV-D). Local sequence variation, particularly in the $5^{\prime}$ UTR, characterized each isolate within regions associated with the pathogenic potential for other picornaviruses. Parallel RNA structure comparisons defined several $5^{\prime}$ and $3^{\prime}$ elements as common to all isolates and unique to the HRV. Motifs like the AUG-presenting 5' ORF initiation stem, or the UAG-presenting $3^{\prime}$ stem, may
contribute to HRV-specific IRES translation mechanisms, ORF termination, or polymerase recognition. We also found embedded within multiple sequences, including recent field isolates, clear evidence for repeated, historical genome recombination. Coinfection with multiple HRVs is known to occur (28), and we now know that this can lead to strains that may have distinct biologic properties and clinical characteristics. The required host environment for HRV recombination is not known, but with complete genome sequences from additional patient isolates such factors may become apparent. Our repository data set provides a baseline framework for the analysis of additional HRVs that may be in communities, including the HRV-Cs, and will enable larger-scale studies of basic molecular and evolutionary characteristics and assignment of disease phenotypes to specific genome regions. The clustering of small clades, the recombinations, and the mutations found in all regions of these genomes suggest that future HRV epidemiologic studies might benefit from full genome sequencing rather than the more limited serotyping. With such an approach, correlations may be more informative in inferring pathogenic potential and in designing antiviral agents and vaccines.

# Photodegradable Hydrogels for Dynamic Tuning of Physical and Chemical Properties 

April M. Kloxin, ${ }^{1}$ Andrea M. Kasko, ${ }^{1,2 *}$ Chelsea N. Salinas, ${ }^{1}$ Kristi S. Anseth ${ }^{1,2} \dagger$

#### Abstract

We report a strategy to create photodegradable poly(ethylene glycol)-based hydrogels through rapid polymerization of cytocompatible macromers for remote manipulation of gel properties in situ. Postgelation control of the gel properties was demonstrated to introduce temporal changes, creation of arbitrarily shaped features, and on-demand pendant functionality release. Channels photodegraded within a hydrogel containing encapsulated cells allow cell migration. Temporal variation of the biochemical gel composition was used to influence chondrogenic differentiation of encapsulated stem cells. Photodegradable gels that allow real-time manipulation of material properties or chemistry provide dynamic environments with the scope to answer fundamental questions about material regulation of live cell function and may affect an array of applications from design of drug delivery vehicles to tissue engineering systems.

Hydrogels are hydrophilic polymers swollen by water that are insoluble owing to physical or chemical cross-links. These waterswollen gels are used extensively as biomaterials for complex device fabrication (1), cell culture for

[^1]tissue regeneration (2), and targeted drug release (3). Often, sophisticated control of the gel structure in space and time is required to elucidate the dynamic relationship between biomaterial properties and their influence on biological function $(4,5)$. For example, progenitor cells are often expanded and differentiated in hydrogel microenvironments, and researchers have demonstrated how the initial gel properties, including mechanics $(6,7)$ and chemical functionality ( 8 ), influence cellular fate. In regenerative medicine, the structure and composition of gels are also regulated temporally, through hydrolytic (9) and enzymatic (10-12) degradation mech-
anisms, to promote cell secretory properties and encourage the development of tissue-like structures in vitro and in vivo. A major challenge is determining which biochemical and biophysical features must be presented in a gel culture environment.

Hydrogel structure and functionality have evolved from the direct encapsulation of cells in simple homogeneous materials to those with highly regulated structures spanning multiple size scales [e.g., through self-assembly (13) or microengineering (14)]. These hydrogel structures are further modified locally by cells with the synthetic incorporation of bioresponsive functionalities (15) or externally by advanced patterning to create spatially varying functionalities. For example, the chemical patterning of a gel by the addition of a second, interpenetrating network or peptide tether has been demonstrated by diffusing chemical moieties into a gel and covalently linking these functionalities to the network by photocoupling (10) or reaction with a photolytically uncaged reactive group (17). Although these are important advances, such processes do not allow modulation of the gel chemistry in real time or photodegradation of the gel structure. Few synthetic materials provide a cellular microenvironment in which physical or chemical cues are initially present and subsequently regulated on demand. We have synthesized monomers capable of polymerizing in the presence of cells to produce photolytically degradable hydrogels whose physical or chemical properties are tunable temporally and spatially with light. The desired gel property for altering cell function or fabricating a

## Materials and Methods

## HRV samples and preparation of viral nucleic acids

The HRV reference repository was considered to include all unique HRV serotypes available from American Type Culture Collection (Manassas, VA, (http://www.atcc.org). These amounted to a total of 99 HRVs, as the previously designated "HRV-Hanks" is now considered hrv-21, hrv-87 is now classified as a strain of EV-86, a serotype within the human enterovirus D species, and hrv-1b and hrv-1a are now considered hrv-1. One described HRV serotype (hrv-57) was not available from ATCC and we utilized a field sample whose sequence was consistent with regions of the hrv-57 genome that had been previously reported. Additional field samples were obtained from the Wisconsin State Laboratory of Public Hygiene (Madison, WI) collected from 2005-2006. These isolates were amplified in HeLa cells, the virus was concentrated, then snap frozen. Full genome sequencing was performed as described below with $10^{5}-10^{6}$ virions from the contents of one vial of frozen virus provided by the aforementioned sources. Briefly, viral RNA and DNA was prepared in a manner previously described in detail (S1-S3) with minor modifications. Each biological sample was first spun to remove cellular debris and processed through a $0.22 \mu \mathrm{M}$ filter to enrich viral particles in the flow-through while retaining bacteria and other cells in the filter. To eliminate residual nucleic acid contaminants in the filtrate, 100 units of DNAse I and $3 \mu \mathrm{~g}$ RNAse A were added to the viral resuspension, followed by incubation at $37^{\circ} \mathrm{C}$ for 1 hour. RNA was extracted with Trizol-LS reagent (Invitrogen, Carlsbad, CA) according to the manufacturer's instructions. The RNA pellet was resuspended in $20 \mu \mathrm{l}$ of nuclease-free water.

## Construction of a library of random PCR fragments and sequencing

The extracted RNA was processed as previously described (S1-S3). Briefly, 800 ng of purified RNA was reverse-transcribed with SSII Reverse Transcriptase (Invitrogen) using the FR26RV-N primer ( $5^{\prime}$ GCC GGA GCT CTG CAG ATA TCN NNN NN 3') at a concentration of $1 \mu \mathrm{M}$. In addition, primer FR40RV-T ( $5^{\prime}$ GCC GGA GCT CTG CAG ATA TC (T)20 $3^{\prime}$ ) was added at a concentration of 5 nM to specifically amplify the polyadenylated $3^{\prime}$ end. The second strand was synthesized by addition of Klenow exo-polymerase (New England Biolabs, Ipswich, MA) in the presence of the FR26RV-N random primer. To capture the $5^{\prime}$ end, the Klenow reaction was supplemented with $10-30 \mathrm{nM}$ of primers FR30RVA (5' GCC GGA GCT CTG CAG ATA TC TTA AAA CTG G $3^{\prime}$ ) and FR30RVB ( $5^{\prime}$ GCC GGA GCT CTG CAG ATA TC TTA AAA CAG C $3^{\prime}$ ) where the final 10bp match the $5^{\prime}$ ends of A-type and B-type rhinoviruses, respectively. PCR amplification used high fidelity Taq Gold DNA polymerase (Applied Biosystems, Foster City, CA) with the FR20RV primer (5' GCC GGA GCT CTG CAG ATA TC $3^{\prime}$ ). PCR amplicons were A-tailed with dATP and 5 units of DNA polymerase (Invitrogen) at $72^{\circ} \mathrm{C}$ for 30 minutes. A-tailed PCR amplicons were fractionated on a $1 \%$ agarose gel and fragments between 500 and 1000 nt were extracted. Amplicons were ligated en masse into the Topo TA cloning vector (Invitrogen) and transformed into competent one-shot Topo top 10 bacteria (Invitrogen). Cells were plated on $\mathrm{LB} / \mathrm{Amp} / \mathrm{XGal}$ agar, and individual colonies were picked for sequencing. The inserted fragments were sequenced bidirectionally with the M13 primers from the Topo TA vector. We routinely sequenced a total of 192 fragments or more per library. Sequencing reactions were performed at the Joint Technology Center (Rockville, MD) on an Applied Biosystems 3730 xl sequencing system with Big Dye Terminator chemistry (Applied Biosystems).

## Assembly of Viral Genomes

Sequence reads were downloaded, trimmed to remove primer sequence as well as low quality sequence, and assembled with the program ELVIRA, the Executive for Large-scale Viral Assembly (http://sourceforge.net/projects/elvira). Additional manual inspections identified ambiguities or potential single nucleotide variants and were interrogated by further RT-PCRs, cloning, and sequencing. To close gaps between assembled contigs, strain-specific primers were utilized. Additional primer design, cDNA synthesis and sequencing were performed to ensure at least 4X sequence coverage along all genomes.

## Polyprotein and RNA genome alignments

Founder data for the HRV polyprotein alignment are from superimposition of virion crystal structure hydrogen-bonding maps as described (S4). Profile hidden Markov models, derived from the founder data, were progressively augmented with published sequences and those derived from this study. The HMMER program suite (Accelrys, San Diego, CA) reported both high and low road fits, building the alignment possibilities with additions from highest to lowest similarity. Each insertion and deletion (indel) in the output iterations was examined and eased within the confines of its high road and low road fits, to maximize conservation of viral cleavage sites, catalytic sites, determined structure landmarks ( $\mathrm{P} 1,2 \mathrm{~A}, 3 \mathrm{~B}-3 \mathrm{D}$ ) and sequence similarity. The HMM profile of composite HRVs was used to fit 3 additional HEV-C out-group sequences into the final alignment. Reverse translation of the polyprotein alignment relative to the original RNA sequences formed a core ORF alignment with analogous indels. Preliminary tree-building exercises identified 20 sequences representative of the dominant HRV clades,
including 3 examples from the putative HRV-C species. The complete genome of each select sequence was analyzed separately by mFOLD (S5). The consensus topography (optimal plus 100 suboptimal structures) for each the $5^{\prime}$ and $3^{\prime}$ regions of each fold was superimposed into common alignments which maximized analogous base-pair superimposition ( $5^{\prime}$ cloverleaf, IRES, $3^{\prime}$ stems, etc.) and minimized indels. These foundations were converted into HMM profiles to which the remaining UTR sequences of all HRV and out-groups were fit. In the interest of alignment length, the HEV-C out-group sequences were truncated to remove a $5^{\prime}$ fragment without analog in the HRV (100 b ribosome read-through, $5^{\prime}$ to ORF AUG). The 5', ORF and 3' aligned segments for all included sequences were joined contiguously into full-length genome alignments. Again, each indel in the file was re-examined for plausibility, consistency and biological conservation, before the composite alignment was finalized.

## Phylogenetic Analysis

Phylogenetic analyses on the polyprotein and genome alignments (msf file format) were conducted with MEGA version 4 (S6) and PhyML version 2.4.5 (S7). HRV sequences from this study (including field strains) were augmented as needed with published data to include at least one representative of the 99 described HRV-A and HRV-B serotypes, and all available (fulllength) data from the HRV-C. Multiple tree iterations were evaluated for both the protein (single gene and polyprotein) and RNA genome data, with UPGMA (MEGA), maximum parsimony (MEGA), neighbor joining methods (MEGA) with bootstrap tests (2000x), and maximum likelihood (PhyML) with approximate likelihood ratio tests (minimum of SH-like and Chi2based aLRT). None of these methods showed significant topological differences for major branch points with p-values $>2$ (i.e., $2 \%$ change), especially if the 3 rd positions of the ORF
codons were omitted from consideration in the RNA trees. In the absence of full-genome data for all reference strains, HRV relationships have been approximated according to more limited sequence sets derived from the VP1, VP0, IRES and 3D regions. To determine whether "serotype" (i.e., VP0 or VP1 sequences) and/or other more conserved regions of the genomes (i.e., IRES or 3D gene) were useful indicators of the full strain relationships, defined maximum likelihood (ML) topologies optimal for these regions were compared statistically with the ML full-genome tree. Optimal ML topologies for the VP1-only (966 b), 3D-only (1389 b), IRESonly ( 547 b) and VP0-only ( 86 b VP4 +352 b VP2) fragments within the RNA alignment were computed within PhyML, then compared individually against the optimal topology of the fullgenome ML tree using PAML and the CONSEL (V0.1i) suite of programs (S37). The tested (null) hypothesis was the expectation that the HRV relationships established using only these limited (albeit commonly used) regions of sequence would be similar to those derived from full genome data. See also the legends to Fig. S6A, B for specific definitions of the implemented topology tests.

## $5^{\prime}$ - and $3^{\prime}$-structural predictions

We considered the accepted notion that thermodynamically derived models for phylogenetically related viruses should exhibit common RNA structural motifs, if such motifs are required for biological activity. Our approach has been previously described in detail (S5). Briefly, rather than form structure predictions on the basis of sequence similarities, folding was undertaken first, and then we searched among the most probable configurations (energy minimization) for regions with consistent structures. As described above for the RNA alignments, full genome sequences for 20-40 hrv, representing different phylogenetic clades,
were evaluated in their entirety by mFOLD (S5) asking for the optimal, and up to 100 closely related (+12 Kcal) suboptimal configurations. Without exception, the consensus fold for each sequence (required $>80 \%$ of queried connect files) agreed that the $5^{\prime}$ and $3^{\prime}$ ends of each RNA generally configured independently. That is, few if any segments within these regions made preferred (low energy) long-range contacts with interior portions of the genome. The UTR topologies folded regionally as a series of local, connected motifs. This tendency was confirmed by assessing the P -num values, computed for the whole-genome folds. The pairing number ( $\mathrm{P}-$ num) is a quantitative measure of the propensity of any given base to become involved with the same or alternative pairing partners in a collection of suboptimal folds. We have shown for other viral sequences that low P-num bases and their correlate partners usually dominate the most important helices and stems supporting biologically significant motifs, especially within the lowest energy configurations. These bases and their partners were therefore used to identify and align true homologues (functional analogues) at the primary sequence level, even in regions with less-than obvious conservation. Superimposition of the $5^{\prime}$ and $3^{\prime}$ low P-num motifs from the genome folds formed the core consensus profiles for the RNA alignments in these regions (as described above) and also identified multiple specific conserved motifs throughout the genomes. Once these commonalities were identified for the $5^{\prime}$ cloverleaf, IRES, $5^{\prime}$ ORF initiation stem, cre element, and $3^{\prime}$ UTR, all other sequences in the alignment were re-folded in these regions (mFold, with 50 suboptimals), to confirm that they too had similar, conserved, low energy, low P-num motifs.

## Recombination analysis

The recombination predictions of the genomic sequences, aligned as described above, were conducted with a suite of programs within the RDP3 package (S8). The individual programs RDP (S9), Bootscan (S10), Maximum X2 (S11), Chimaera (S8), SiScan (S12) and 3Seq (S13), were implemented for the analysis. Since no single program provides optimal performance under all conditions, any event supported by evidence from two or more analyses with P-values $<0.00001$ was considered a result consistent with recombination. Potential recombination events were also assessed by phylogenetic analysis, breakpoint polishing and alignment consistency checks. For each individual program, default settings were used except as specified: RDP, internal reference only, window size for recombination, 100 bp with step size 10 bp; GENECONV, G-scale was set as 3; BootScan, number of bootstrap replicates, 200, window size, 100 bp , step size, 10 bp , model options: Jukes and Cantor, 1969; Maxichi, variable window size was used, strip gap was selected; SiScan, window size, 100 bp with step size 10 bp , P -value permutation number was set as 1000. In additional analyses, to confirm the recombinations that were found, genomic sequences were aligned using progressive alignment methods (S14). Briefly, the progressive alignments were performed with non-coding (S15) and coding regions (S14, S16) using the referenced programs and the alignments were concatenated by a custom script. The subsequent final alignment was utilized for recombination predictions using the RDP3 package as described above.

Fig. S1. Whole genome amino acid sequence identity comparison. Amino acid sequences were deduced from the coding region of the sequenced Rhinovirus genome sequences. The aligned amino acid sequences were compared in a pairwise fashion to calculate the identities. The identity matrices of the compared genomes visualized in square arrays of sequence identity values were clustered by the phylogenetic ordering.

Figure S2: A: An HRV genome map. The 5' untranslated region (5' UTR) is linked to VPg(3B), and encodes several important RNA structures which function during RNA synthesis and genome translation. The single open-reading frame (ORF) encodes a polyprotein, which is cleaved in a series of co-translational and post-translational reactions to provide all mature viral proteins required to establish and perpetuate an infection. The capsid proteins (red) and proteins involved in replication functions (blue) are common to all HRV, and all sequences share analogous cleavage sites delineating these locations in the polyprotein. The illustrated genome is hrv-35; the base numbering system in this panel is for that sequence. B: The HRV sequences in the RNA genome alignment (Table S2) were queried pairwise at each position in the alignment. All sequences were given equivalent weight. The arithmetic average of the scores ( 0 or 1 for each pair) was reported for each position, re-averaged over a sliding window of 30 adjacent residues (+/-15), then plotted relative to the alignment as a whole. The strongest sequence conservation is in the $5^{\prime}$ IRES region. The lowest conservation is in the 5 ' spacer region, upstream of the IRES, and also in the capsid coding regions, where the 1B, 1C and 1D troughs correspond to the respective, mapped immunogenic surface loops. The averaged identity across all HRVs, considering all alignment positions, is indicated with the blue, horizontal line.

Figure S3 A: Cloverleaf-like 2D RNA structures dominate the 5' ends of all HRV genomes. A representative structure for each species is depicted. The cloverleafs bind host and cellular proteins required for the initiation of viral RNA synthesis and also aid in the regulation of ribosome entry onto the upstream IRES (internal ribosome entry site). Adjacent to the cloverleaf all HRV have a pyrimidine-rich tract. In related polioviruses, this tract binds PCBP2, a cellular factor needed for viral RNA synthesis and IRES-dependent translation. However, the specific sequence in this region is virtually unique to every known isolate of HRV, varying even among field-strains of the same serotype. Examples of the length and sequence diversity among HRVs are shown for each genus (blue). The flanking sequences (green) are alignment landmarks, common to all HRVs. The 5'-most nucleotide of every picornavirus is "U" and it is linked by a tyrosine-phosphodiester bond to viral protein VPg (3B).

Figure S3 B: Region Between IRES and ORF Start Codon (AUG)

Figure S 3 B : The RNA structures near the AUG which begins the polyprotein open-reading frame (ORF) are depicted for representatives of each HRV species. Every sequenced HRV folds this region into a similar configuration when the genome is probed by minumum-free energy calculations. The ORF AUG (white letters, green box) is always paired with a conserved upstream AUG (light green box), which marks the 3' boundary of the IRES. Other species in the Enterovirus genus do not make similar pairings. Rather, other enteroviruses are believed to launch their ribosomes for scanning, from the upstream AUG. This HRV configuration makes it likely that an IRES-bound ribosome could readily "switch" to the ORF AUG, without scanning the intervening spacer. Between these AUGs, neither the specific sequence or it's length is well conserved among HRVs. Rather, all form these related structures, preserving the specific pairings only in the region of the AUGs.

| 2 A protein | 2C protein | 1B protein cre? | 1B protein cre? |

Figure S3 C: Picornavirus RNA synthesis is protein primed. The viral RNA polymease 3Dpol, uridylylates protein 3B (VPg) to form VPg-pUpU, then uses this protein:RNA as primer for the initiation of positive and negative strand RNA synthesis. The uridylylation reaction is templated by a special RNA structure called the cre (cis-acting replication element) whose location varies for every known species of picornavirus. For the HRV-A, the cre has been mapped within the genome region encoding the 2A protein. For the HRV-B, the cre is within the 2 C region. The HRV-C cre has not been mapped genetically, but common to all cres, is a distinct stem motif, displaying CAAACAA or a closely related sequence. Within the sequenced genomes of the HRV-C there are 2 locations in the 1B gene which fit this description. These, and the HRV-A and HRV-B cres are depicted. The structure is for the indicated sequence. Those bases colored red are conserved among all other sequences in that species. All observed (aligned) base changes are indicated in blue. Below each element is the protein sequence encoded by that region. Red residues are conserved among all sequences in that species. Blue residues are observed in at least 1 other sequence. Note: the HRV-A structure omits sequence variation contributed by the clade-D viruses. It is not yet clear whether the cre for these viruses occupies the same genome location.

Figure S3 D: 3' Untranslated Regions (3' UTR)

Figure S3 D: Representative HRV genomes were analyzed for their minimum free-energy configurations. Within those datasets, the regions representing the 3 ' untranslated regions ( $3^{\prime}$ UTR) fold into motifs independent of the rest of the genome. Examples of these regions, typical of each HRV species are illustrated (ORF terminator, red box, white letters). In every case a single stem motif dominates the region, ending exactly at the 3 ' poly(A) tail, which may contribute 1-2 additional base-pairs to the bottom of the stem. Sequence conservation is poor throughout this region, but every virus, with the exception of the clade-D isolates, displays a termination codon within the terminal loop of the 3' stem (tan box, red letters). Although multiple other termination codons are scattered frequently throughout the region (tan boxes), this particular triplet is the only one which is conserved among most of the isolates, regardless of species. The clade-D viruses (e.g. hrv-95) have shorter 3' stems and display an UAG triplet near, but not within the terminal loop (Fig S4).

Figure S4: Among the HRV-A, 3 serotypes (hrv-08, hrv-45 and hrv-95) form a distinct clade, called "clade-D", Of these, hrv-08 and hrv-95 share $>98 \%$ nucleotide identity, perhaps indicating a misidentification within the original reference collection. Despire the paucity of unique isolates in this clade, the identified members share characteristics in certain key genome locations which clearly distinguish them from all other HRV-A sequences (or HRV-B and HRV-C). A few examples are shown in this figure. A: Near the C-terminus of the 2A protein, in a region known to contribute to substrate specificity, all clade-D viruses have an indel unique among all other HRV. B: Throughout the alignments, there are numerous locations, like this one in the 3Dpol gene, where clade-D sequences vary independently with highly variant, non-synomous substitutions. C: The cre elements of all HRV-A are located 2A gene (see Fig S3C). The loop sequences, especially in the essential terminal loop invariably display ACAAACAA motifs providing the template for 3 D -dependent VPg uridylylation. The "G" residue (red) displayed within the clade-D loop has not been observed in any other functional cre element. This may indicate that for this clade the (authentic) cre lies elsewhere in the genome, or that these particular cres have a different templated activity. D: The 3' UTR sequences of all HRVs, with the exception of the clade-D viruses, display a conserved termination codon in the terminal 5-6 b stem loop (Fig S3D), and moreover, there are very few examples of extended interior loops within the terminal stem. The clade-D viruses pair the conserved termination codon, near the top of the stem, and display a second, unpaired codon, within an interior loop (tan boxes, red letters). They are also the only sequences to have just 4 b in the terminal loop. This entire 3 ' configuration is unique to this clade, and not shared by any other HRV-A, HRV-B or HRV-C.

(color keys for amino acids)

Figure S5. The distribution of amino acid variations in field samples. Each field sample was aligned with the reference sample of the same serotype. Amino acid differences in the field sample are designated by color changes as identified in the key at the bottom of the figure. The upper panel portrays a diagram of hrv-14 genome structure for orientation.

Figure S6b. The serotype of an HRV is determined by sequences within the immunogenic surface loops of capsid proteins VP0 (VP4+VP2) and VP1. Frequently, these segments and/or the IRES and/or the 3Dpol regions are sequenced separately and used to place new isolates onto HRV species trees. Established statistical methods within the program set CONSEL (V0.1i) tested the null hypothesis that the topology (Fig S6c) of such "serotype only" trees, or an IRES-only tree, or a 3D-only tree were consistant with the Fig S6a full genome ML tree. The program output includes: the observed log-likelihood difference (obs); the p-value of the approximately unbiased test calculated from the multiscale bootstrap (au); the bootstrap probability calculated from multiscale bootstrap (np); the bootstrap probability calculated in the usual manner (bp); the Kishino-Hasegawa test (kh); the ShimodairaHasegawa test (sh); the weighted Kishino-Hasegawa test (wkh); and the weighted Shimodaira-Hasegawa test (wsh). The last 6 tests had identical output values for all considered trees, and are summarized together. The data, individually and collectively strongly reject the null hypotheses for all alternative tested topologies.

Figure S6a. The RNA genome alignment (TableS2) was augmented with additional outgroup sequences from the HEV-C species (pv2l:M12197, pv31:K01392) and the HEV-B species (cvb1:M16560, cvb2:AF081485, cb3:M33854), with profile:profile fits in Clustal. A maximum likelihood (ML) tree was calculated using PHYML version 2.4.8for the full genome dataset ("full"). TN93 nucleotide substitution model gave the best likelihood (loglk -462223) over HKY, GTR, JP69, K2P and F81 models. TheTs/tv ratio and invariable sites were estimated. Approximate likelihood ratio tests (aLRT, minimum of SH-like and Chi2-based values) and bootstrap tests (BS, 200x) were applied. The test values label the tree nodes (gray text, \%BS:aLRT). Tree length (sum of branch lengths) is 19.39. When compared to the Fig 2 neighbor-joining ( NJ ) tree, terminal clades were collapsed if they were identical to the NJ tree. Of all considered linkages, only hrv78 and the hrv $(31+47)$ clade showed minor rearrangements by ML analyses relative to NJ (thin line branches). Parallel ML trees were also calculated using only the VP1, VPO, IRES or 3D-encoding RNA sequences (see Methods). Taxa names with different clade affiliations ( $>0.2 \mathrm{p}$-value) on the VPO-only tree are shown in red. Taxa names with different clade affiliations on VP1-only tree are highlighted in blue.

Figure S6C. The five specific maximum likelihood (ML) tree topologies tested in panel S6b are indicated.

## Table S1 Legend

(1) Order in which these sequences are listed in accompanying protein (TableS3) and RNA (TableS2) alignment files.
(2) Designation of Human Rhinovirus-C (HRV-C) as a species has been accepted by the ICTV Study Group on Picornaviruses.
(3) Field strains were assigned serotypes on the basis of sequence similarity to reference (ATCC) strains.
(4) Strain designation from GenBank sequence description if available; ATCC origin; or field-strain isolate from this study.
(5) Protein and RNA alignments use these names. Accession number, if available, precedes serotype; f01-f10: field strains; entries beginning with "hrv-" are from this study.
(6) (abbreviated) Strain names used on phylograms. Not all alignment entries are included (not inc). Asterisk (*) designates GenBank origin, sequence is not original to this study.
(7) GenBank accession numbers for published genomes (black) or from this study (green). Pico-01, pico-09 and pico-85 genomes were pieced from the indicated GenBank fragments (see accession numbers) according to linkage guides on The Picornavirus Database (Pico-DB) at: http://www.picornaviridae.com/
(8) The Major (M) group HRV use ICAM-1 receptors. The Minor (m) group HRVs use LDLR-like receptors. See reference: (S35).
(9) Drug group reactivity according to reference: (S36). na: not part of that study.
(10) $\quad 1^{\text {st }}$ base of polyprotein open reading frame within individual sequence file.
(11) Last base of polyprotein open reading frame within individual sequence file. Count excludes the ORF termination codon.
(12) Polyprotein length, in amino acids, encoded by this genome.
(13) Genome sequence length (as available) as it is included within TableS2 alignment file.
(14) 3 ' non-coding fragment length, as included in TableS2 alignment file. Count does not include poly(A).
(15) cg: complete genome. cg-5: almost complete genome, except for 5' end.
(16) Chimeric sequence: bases 1-135 from this study, remainder from EF077279.
(17) Thomas Briese and lan Lipkin, personal communication to ACP.
(18) First entry of TableS2 and TableS3 alignments include an annotation line with protein structure features, polyprotein cleavage sites, ORF start/stop, etc.

 results using the indicated analysis modes．The nucleotide is referenced to the recombinant（daughter）hrv．See Fig． 3 for representative
